

Repository Pattern

The Repository Pattern is where you define your operation on how you will interact with a data source in a repository. A data source could be a local database, or remote server such as a REST API.

The main purpose of this pattern is to separate the way we store or retrieve data with how we use data by the business logic. By separating this, the codebase is more organized, easy to maintain, and enhances its scalability.

Benefit is changing data source, all you have to do is swap out the data source. Your business layer won't know the difference because it never actually interacts with the data source in the first place, it only deals with the repository.

Secondly, using the Repository Pattern will save you loads of time in testing as you create fake repositories.
